Communicated by Peter Oefner
A collaborative work was carried out by the Spanish and Portuguese ISFG Working Group (GEP-ISFG) to estimate Y-STR mutation rates. Seventeen Y chromosome STR loci (DYS19, DYS385, DYS389I and II, DYS390, DYS391, DYS392, DYS393, DYS437, DYS438, DYS439, DYS460, DYS461, DYS635 [GATA C4], GATA H4, and GATA A10) were analyzed in a sample of 3,026 father/son pairs. Among 27,029 allele transfers, 54 mutations were observed, with an overall mutation rate across the 17 loci of $1.998 \times 10^{-3}(95 \%$ CI, $1.501 \times 10^{-3}$ to $2.606 \times 10^{-3}$ ). With just one exception, all of the mutations were single-step, and they were observed only once per gametogenesis. Repeat gains were more frequent than losses, longer alleles were found to be more mutable, and the mutation rate seemed to increase with the father's age. KEY words: mutation rate; Y-chromosome; Y-STR; microsatellite

## INTRODUCTION

Microsatellites have been widely used as genetic markers in a variety of studies and applications [e.g. Ohashi and Tokunaga, 2003; Jobling and Tyler-Smith, 2003; Sun et al., 2003], in addition to being the focus of research on their own. Their high degree of polymorphism is due at least in part to the relatively common occurrence of mutations. This particular feature is especially appropriate for microevolutionary studies [e.g., Jorde et al., 1997; Brinkmann et al., 1998a], but is not so welcome in other applications, such as forensics [Kayser and Sajantila, 2001; Jones and Ardren, 2003]. In any case, even if microsatellites ceased to be used as genetic tools, their evolutionary dynamics would be an important research field by itself. In this context it is of particular
importance to improve our knowledge concerning the mechanisms and rates of mutation.

Published online 11 October 2005 in Wiley InterScience (www. interscience.wiley.com).

During the last decade, over 200 Y short tandem repeat (STR) polymorphisms have been described [Kayser et al., 2004]. Y chromosome-specific STR analysis has been extensively applied to human migrations and evolution, as well as to forensics [e.g., Zhivotovsky et al., 2004; Jobling et al., 1997].

Studies on Y-STR mutation rates are scarce and have considered only a restricted number of markers [Heyer et al., 1997; Bianchi et al., 1998; Kayser et al., 2000; Dupuy et al., 2004; Kurihara et al., 2004; Ballard et al., in press; Budowle et al., 2005]. STR mutation rates present both inter- and intralocus variations, depending on the locus structure and allele length [e.g., Brinkmann et al., 1998b; Di Rienzo et al., 1998]. A large amount of data are necessary to reliably estimate allele-specific mutation rates, which is essential for consistent dating of Y-SNP defined lineages (haplogroups) and data interpretation in kinship analysis.

Therefore, in the present work we aimed to increase the amount of data regarding mutations at 16 Y -STR (corresponding to 17 loci, since DYS385 includes two loci) by compiling the results obtained from confirmed father/son pairs, in 17 different laboratories, by members of the Spanish and Portuguese Working Group of the International Society for Forensic Genetics (GEP-ISFG).

## MATERIALS AND METHODS

Samples were obtained from 3,026 father/son pairs from paternity cases in 17 different laboratories from Argentina, Brazil,

Colombia, Portugal, Spain, and Venezuela. The biological relationship of all father/son pairs was previously confirmed by using autosomal STRs, with paternity index values above 10,000.

Each laboratory used its own routine methods for DNA extraction, PCR amplification and detection, and sequence analysis. All of the mutations were confirmed by a second typing in a different laboratory from the one in which they were detected by sequence analysis.
The STR alleles of the "minimal haplotype" loci (i.e., DYS19, DYS385, DYS389I and II, DYS390, DYS391, DYS392, and DYS393) were named as in the Y-STR Haplotype Reference Database (YHRD; www.yhrd.org), and alleles in the other loci were named according to Gusmão et al. [2002].

Confidence intervals (CI) for mutation rates were estimated from the binomial standard deviation (SD). Locus- or allelespecific mutation rates were tested for departures from the mean by successively comparing each locus (or allele) against all others pooled through a contingency table chi-square test.

## RESULTS

Results were compiled from 17 participating laboratories that typed five to 16 Y-STRs in five to 1,238 meioses (Table 1). In 27,029 allele transfers, 55 mutations were observed: one at DYS438; two at DYS389 I, DYS389 II, DYS393, DYS437, and GATA H4; three at DYS390, DYS392, and DYS635; four at

*DYS389 II-I corresponds to the number of repeats obtained when DYS389I repeat numbers are subtracted from those at DYS389II.

DYS460 and GATA A10; five at DYS19 and DYS385; eight at DYS439; and nine at DYS391 (Table 2).
All mutations were confirmed by sequence analysis (Table 3) and found to have occurred inside the repetitive sequence structure, except in one case. One of the five DYS19 mutations occurred at the microsatellite flanking region and thus was not considered in STR mutation rate estimations. With the exception of one case, all mutations were single-step. A four-step mutation at DYS438 was observed. Single-locus mutation rates were estimated for the 16 Y-STRs under study (Table 4) as
the frequency of mutations in the total number of allele transfers. In the case of DYS385, where two loci are simultaneously amplified with one pair of primers, the number of allele transfers was calculated as being twice the number of meioses. The overall mutation rate estimated across the 17 loci was $1.998 \times 10^{-3}\left(95 \% \mathrm{CI}, 1.501 \times 10^{-3}\right.$ to $\left.2.606 \times 10^{-3}\right)$. DYS439 was found to be the marker with the highest frequency of mutations $\left(6.873 \times 10^{-3}\right.$, a value that is outside the $95 \% \mathrm{CI}$ of the one estimated for the overall Y-STR loci mutation rates).
table 2. Mutations Observed at STR Loci With the Respective Father and Son Phenotypes, Paternity Index (L), and Father's Age at the Time When the Son Was Born (Age)

## Interlocus Mutation Rate Analysis

The mutation rates estimated for the 16 Y-STRs obtained by pooling our results with the previously published Y-STR mutation rates are displayed in Table 4. To date, 64,273 Y-STR allele transfers have been studied, with mutations detected at a frequency of $2.100 \times 10^{-3}\left(95 \% \mathrm{CI}, 1.761-2.486 \times 10^{-3}\right)$. The average mutation rate value is similar to the one found in our sample $\left(1.998 \times 10^{-3}\right)$ and slightly lower than those found by Dupuy et al. [2004] and Kayser et al. [2000] (2.3 $\times 10^{-3}$ and $2.8 \times 10^{-3}$, respectively), although not significantly different.

In our sample, locus-specific mutation rates varied between $0.824 \times 10^{-3}$ at DYS438 ( $95 \%$ CI, $0.021-4.585 \times 10^{-3}$ ) and $6.873 \times 10^{-3}$ at DYS439 ( $95 \%$ CI, $2.972-13.497 \times 10^{-3}$ ). When our results are pooled with published data, a few significant differences between the locus-specific mutation rates emerge (Table 4). When compared by means of chi-square tests, after Bonferroni correction for multiple testing, three loci show significantly divergent rates: DYS392 is less mutable ( $\mathrm{P}=$ 0.006 ), while DYS391 ( $\mathrm{P}=0.009$ ) and DYS439 $\left(\mathrm{P}=7 \times 10^{-4}\right)$ tend to mutate faster. Since all of the STRs studied here are repetitions of tetranucleotides, with the exceptions of DYS392 (tri-) and DYS438 (penta-), it is premature to make comparisons between the mutation rates and the repeat motif length.

## Intralocus Mutation Rate Analysis

It is worth mentioning that since most of the samples were of Iberian origin, one can expect a high proportion of the chromosomes ( $>50 \%$ ) to belong to haplogroup R1b [Jobling and Tyler-Smith, 2003], and different mutation rates can be expected in different haplogroup backgrounds. Nevertheless,
according to Dupuy et al. [2004], differences in haplogroupspecific mutation rates are not significant when the standardized allele length is taken into account. Therefore, allele-specific mutation rate estimates can be reliably used to predict Y-STR mutation rates in different haplogroups.

In most cases, mutations occurred at the most frequent alleles in the fathers' sample (Tables 1 and 2). However, sample sizes per allelic classes at each STR are not sufficient to allow for an accurate estimation of allele-specific mutation rates.

Allele-specific mutation rates were estimated jointly for loci with uninterrupted TAGA repeats by pooling the data available for tetranucleotide repeats, where the observed length variation and mutations are mainly due to different numbers of these repeats (Table 5). At first glance, the allele-specific mutation rates appear to grow linearly with the length of uninterrupted repeats (Spearman's rho $=0.886, \mathrm{P}=0.019$ ). However, each estimate has its own statistical uncertainty, and actually only the mutation rate for alleles with 13 repeats is significantly different from that of all other alleles combined ( $\mathrm{P}=0.0013$ ). Pooling alleles into short ( $<11$ homogeneous repeats) and long ( $\geq 11$ repeats) classes, the short class shows a rate that is 3.06 times slower than that of the long class ( $\mathrm{P}=0.0032$, Table 5). In summary, a trend for higher mutability is confirmed for longer alleles, although a finer determination of this relationship would require the use of larger samples.

## Mutation Directions and Sizes

In accordance with results by Kayser et al. [2000], Dupuy et al. [2004], Kurihara et al. [2004], Ballard et al. [in press], and Budowle et al. [2005], we found a significantly higher number of

${ }^{*}$ Segments that are not included in the allele nomenclature are in bold letters.
${ }^{\text {a }}$ Mutation at flanking region.
gains (36) vs. losses (18) of repeats ( $\mathrm{P}=0.014$; Table 6A). Only one out of 54 mutations was not single-step. When all of the data available on Y-STRs were combined, $95.6 \%$ of the 135 reported mutations were single-step, which in general supports a strict stepwise mutation model. Conversely, the fraction of non-singlestep mutations was $4.4 \%$ ( $95 \%$ CI, $1.0-7.9 \%$ ). In the pooled data set, single repeat gains are over twice as frequent as losses, and the difference is highly significant $\left(\chi^{2}=15.710, \mathrm{P}=7.4 \times 10^{-5}\right)$.

To correlate allele length and mutation direction, the frequency of repeat gains vs. losses was counted for different numbers of repeats at the motif where the mutation occurred (Table 6B). Since the number of mutations was low, differences in repeat gains vs. losses were tested by pooling some contiguous alleles into size classes. No clear patterns emerge from this analysis, since gains were significantly more frequent than losses at allele classes 9-10 $\left(\mathrm{P}=5.3 \times 10^{-4}\right), 11(\mathrm{P}=0.0038)$, and $14-16(\mathrm{P}=0.0067)$, but not at classes $6-8,12$, or 13 . Therefore, the available data do not provide evidence for the hypothesis that an excess of repeat losses at longer alleles would prevent the indefinite expansion of STR allele length [Dupuy et al., 2004].

## Father's Age

Table 7 shows the age distribution of the parents involved in the mutation events, as well as the age-group-specific mutation
rates. Considering each mutation event, the average age of the fathers involved was 37.3 years ( $\mathrm{SE}=1.82$ ); likewise, for nonmutated transmissions, the average age was 31.30 years ( $\mathrm{SE}=0.08$ ). This is in contrast with the results obtained by Dupuy et al. [2004], who found no distinction between the ages of fathers with mutations and those of the whole sample. In the present study the difference was significant, by both a t-test $\left(\mathrm{t}=12.326, \quad \mathrm{P}=4.5 \times 10^{-4}\right) \quad$ and Mann-Whitney's U-test $\left(\mathrm{P}=2.7 \times 10^{-4}\right)$. At first glance, the mutation rate appears to increase with the age group (Spearman's rho $=0.657, \mathrm{P}=0.156$ ), although without statistical significance, given that the correlation is based on six points (age groups) only. As for specific age-group rates, the rate for $41-50$ years was higher than the average ( $\mathrm{P}=0.026$ ), while the rest were statistically not significantly different from this average.

## DISCUSSION

Although according to data on autosomal STRs, the male germ line has a higher frequency of mutation events than the female germ line [Weber and Wong, 1993; Brinkmann et al., 1998a], no significant differences were found between the average Y-STR mutation rates and those found in autosomal STRs [Brinkmann et al., 1998b; Henke and Henke, 1999; Sajantila et al., 1999]. Although the average mutation rate estimated in the present
work, across 17 Y-STR loci (Table 4), was slightly lower, it was not significantly different from those determined by Kayser et al. [2000] and Dupuy et al. [2004] in their analyses of father/son pairs. Pooling our data with those already published on Y-STRs, a significantly lower mutation rate at DYS392 (supporting the findings of Nebel et al. [2001]) and a higher mutation rate at DYS391 and DYS439 were found in comparison with the average value (Table 4). The higher mutation rate found at DYS439 explains why this marker is the one that contributes most to the increase in haplotype diversity of the current STR set [Alves et al., 2003]. For TAGA repeats, a trend for higher mutability was confirmed for longer alleles.

All of the observed mutations in our screening were single-step, except in one case out of 54 (Table 6A). These results are in accordance with the generally accepted mutation model for microsatellites, in which the alleles are known to mutate primarily through the gain and loss of single repeat units [Weber and Wong, 1993; Di Rienzo et al., 1994; Zhivotovsky and Feldman, 1995].

Repeat gains were found to be twice as frequent as losses (Table 6A), in agreement with previous observations [Cooper et al., 1999; Kayser et al., 2000; Dupuy et al., 2004; Kurihara et al., 2004] and as expected for young microsatellites [Xu et al., 2000]. When we compared repeat gains and losses in different allele classes, in contrast to Dupuy et al. [2004], we found no evidence

*The number of transmissions and of mutations are smaller than in previous analyses, since father's age could not be recorded in all cases (data from laboratories 1,5 , and 17 were excluded).
for an excess of repeat losses at longer alleles. This supports the notion that this mechanism is biased toward microsatellite expansion [e.g., Primmer et al., 1996; Amos et al., 1996; Brinkmann et al., 1998b] until a certain repeat length at which the rates of expansion and contraction mutations are equal [Xu et al., 2000].

In conclusion, the compilation of Y-STR data for father/son pairs, which is an automatic by-product of the routine work of many forensic laboratories, allows the estimation of increasingly reliable locus/allele-specific mutation rates for the most widely used markers in both the population and forensic genetics. It is timely to compare these estimates with those obtained from phylogenetic inferences [Zhivotovsky et al., 2004], since these approaches use data that are at opposite ends of the evolutionary process. In fact, while analyses of father/son pairs include all viable offspring, phylogenetic data are filtered by long-range selective effects.
